Prices and Output in an Open Economy: Aggregate Demand and Aggregate Supply

LEARNING GOALS:
After reading this chapter, you should be able to:
• Understand how short- and long-run equilibrium is reached under fixed and flexible exchange rates with the aggregate demand and aggregate supply
• Understand how real and monetary shocks, and monetary and fiscal policies, affect the nation’s aggregate demand and equilibrium
• Explain how monetary and fiscal policies can be used to adjust to supply shocks and stimulate growth in an open economy

19.1 Introduction
In our discussion of open-economy macroeconomics, we have generally assumed until now (except briefly in Sections 17.6 and 18.6) that prices remain constant as the economy expands and contracts. Only when the economy reaches the full-employment constraint would prices begin to rise. In the real world, however, prices rise and fall as the economy expands and contracts during the regular course of the business cycle. In this chapter, we relax the assumption of constant prices and examine the relationship between price and output in an open economy. We do so by using an aggregate demand and aggregate supply framework that incorporates the effects of international trade and capital flows.

We begin in Section 19.2 by reviewing the concepts of aggregate demand and aggregate supply, and by showing how equilibrium is determined at their intersection in the short run and in the long run in a closed economy. Section 19.3 then expands the presentation to examine the effect of international transactions on aggregate demand and aggregate supply under fixed and flexible exchange rates. Section 19.4 extends the analysis to examine the effect of real and monetary shocks as well as changes in fiscal and monetary variables on the nation’s aggregate demand. In Section 19.5, we discuss the effect of monetary and fiscal policies in an open economy under flexible and fixed exchange rates. Finally, Section 19.6
focuses on monetary and fiscal policies to stimulate long-run growth and to adjust to supply shocks in open economies.

### 19.2 Aggregate Demand, Aggregate Supply, and Equilibrium in a Closed Economy

In this section, we begin by defining the aggregate demand curve and showing how it is derived from the IS and LM curves of the previous chapter. Then we examine the aggregate supply curve in the long run and in the short run. Finally, we look at how the interaction of the aggregate demand and supply curves determines equilibrium in a closed economy in the short run and in the long run.

#### 19.2A Aggregate Demand in a Closed Economy

The aggregate demand (AD) curve shows the relationship between the total quantity demanded of goods and services in an economy and the general price level, while holding constant the nation’s supply of money, government expenditures, and taxes. This is analogous to an individual’s demand curve for a commodity, except that the AD curve refers to the total quantity demanded of domestic goods and services in the nation as a function of, or with respect to, the general price level or GDP deflator. The aggregate demand curve is downward sloping, indicating that the total quantity of domestic goods and services demanded in the nation is greater the lower the price level.

Figure 19.1 shows how the aggregate demand curve is derived from the IS–LM model of the previous chapter. Recall from Section 18.3 and Figure 18.2 that the IS curve shows the

![Figure 19.1 Derivation of the AD Curve from the IS–LM Curves](image-url)

*Figure 19.1. Derivation of the AD Curve from the IS–LM Curves.*

The intersection of the IS and LM curves at a given price level determines the equilibrium interest rate \( i_E \) and national income \( Y_E \) at point E in the left panel. This defines point E at price \( P_E \) and income \( Y_E \) on aggregate demand curve AD in the right panel. An increase in price from \( P_E \) to \( P' \) reduces the real value of the nation’s given money supply and causes the LM curve to shift to the left to \( LM' \), thus resulting in the lower income level of \( Y' \) at point \( E' \) in the left panel and on the AD curve in the right panel.
19.2 Aggregate Demand, Aggregate Supply, and Equilibrium in a Closed Economy

Various combinations of interest rates (i) and national income (Y) that result in equilibrium in the goods market (i.e., at which the quantity demanded of goods and services equals the quantity supplied). The LM curve, on the other hand, shows the various combinations of i and Y at which the demand for money is equal to the given supply of money, so that the money market is in equilibrium. Both the IS and LM curves are drawn for a given price level. The equilibrium level of national income (Y_E) and interest rate (i_E) is then determined at the intersection of the IS and LM curves (point E in the left panel of Figure 19.1). This defines point E on the aggregate demand curve (AD) in the right panel of Figure 19.1 at the given price level (P_E) and income level (Y_E). Note that both panels measure national income along the horizontal axis, but the right panel has the price level rather than the interest rate on the vertical axis.

Now suppose that prices in the nation rise from P_E to P'_E. This reduces the real value of the given money supply and causes the LM curve to shift to the left to LM'. The intersection of the IS and LM' curves at point E' in the left panel of Figure 19.1 defines the higher equilibrium interest rate of i' and the lower equilibrium level of national income of Y'. Note that the higher price does not directly affect the IS curve because equilibrium in the goods sector is measured in real terms. The higher equilibrium price P' and lower income level of Y' define point E' on aggregate demand curve AD in the right panel. Thus, higher prices are associated with lower levels of national income and result in an AD curve that is inclined downward. The steeper are the IS and the LM curves, the steeper or less elastic is the AD curve.

If prices were held constant and the money supply were changed instead, the entire AD curve would shift. For example, an increase in the money supply for a given price level (easy or expansionary monetary policy) shifts the LM curve to the right and results in a higher level of national income. This can be shown by a shift to the right of the entire AD curve to reflect the higher level of national income at the given price level (see Problem 3, with answer at the end of the book). Thus, national income can rise either if prices fall with a given money supply (a movement down an AD curve) or if the money supply is increased with constant prices (a rightward shift of the AD curve). Similarly, an increase in government expenditures and/or reduction in taxes (expansionary fiscal policy) shifts the IS curve to the right, and this also causes the AD curve to shift to the right, indicating a higher level of national income at each price level. On the other hand, tight or contractionary monetary and fiscal policies shift the AD curve to the left.

19.2b Aggregate Supply in the Long Run and in the Short Run

The aggregate supply (AS) curve shows the relationship between the total quantity supplied of goods and services in an economy and the general price level. This relationship depends crucially on the time horizon under consideration. Thus, we have a long-run aggregate supply curve and a short-run aggregate supply curve.

The long-run aggregate supply (LRAS) curve does not depend on prices but only on the quantity of labor, capital, natural resources, and technology available to the economy. The quantity of inputs available to an economy determines the natural level of output (Y_N) for the nation in the long run. The more inputs are available to the economy, the larger is its natural level of output and income in the long run. Since the long-run aggregate supply curve does not depend on prices, the LRAS curve is vertical at the natural level of output when plotted against prices, as shown in Figure 19.2. Thus, higher prices do not affect
FIGURE 19.2. The Long-Run and Short-Run Aggregate Supply Curves.

The long-run aggregate supply curve (LRAS) is independent of prices and is vertical at the nation’s natural level of output ($Y_N$), which depends on the availability of labor, capital, natural resources, and technology in the nation. The nation’s short-run aggregate supply curve (SRAS) slopes upward, indicating that the nation’s output can temporarily exceed (point A) or fall short (point B) of its natural level (point E) because of imperfect information or market imperfections.

Output in the long run. The only way to increase output in the long run is for the economy to increase the supply of inputs or resources. Since this occurs only gradually over time, we assume no growth in our analysis, at least for now.

The short-run aggregate supply (SRAS) curve, on the other hand, slopes upward, indicating that higher prices lead to larger outputs in the short run (see Figure 19.2). The important question is why does output respond positively to price increases in the short run? And how can output in the short run ever exceed the long-run natural level? The short-run aggregate supply curve is upward sloping (so that the level of output can deviate temporarily from the natural level) because of imperfect information or market imperfections. For example, if firms find that they can sell their products at higher prices but do not realize immediately that input prices have also increased in the same proportion, they will temporarily increase output. As a result, aggregate output increases in the short run, say from point $E$ to point $A$ along the SRAS in Figure 19.2. When firms eventually realize that their costs of production have also increased proportionately, they will reduce production back to its original level, and so aggregate output returns to its long-run natural level but at the higher price level.

Thus, imperfect information or market imperfections can lead to short-run output levels in excess of the nation’s long-run natural level. This is possible by employing workers on an overtime basis and running factories for longer or multiple shifts. Since it becomes progressively more difficult and expensive to continue increasing output in this manner, however, the short-run aggregate supply curve becomes steeper and steeper and eventually vertical (see Figure 19.2). In the long run, firms realize that all prices (and hence their costs)
have also increased proportionately and so they reduce production to the original level, with the result that the output of the nation returns to its lower long-run natural level, but at the higher price level prevailing.

The same can also occur in reverse. That is, if firms find that the prices they receive from the sale of their products have declined but do not immediately realize that the price of all products including their inputs have also fallen in the same proportion (and that their costs of production are also the same), they will cut production, and so the nation’s output temporarily falls below its natural level (point $B$ in Figure 19.2). In the long run, however, firms recognize their error and will increase output to the original long-run natural level (point $E$ in Figure 19.2). The same process can be explained by focusing on market imperfections in labor markets (see Problem 5, with answer at the end of the book).

19.2c Short-Run and Long-Run Equilibrium in a Closed Economy

Given the aggregate demand curve and the short-run and long-run aggregate supply curves, we can examine the short-run and the long-run equilibrium in a closed economy with Figure 19.3. We begin at equilibrium point $E$ at the intersection of aggregate demand curve $AD$, long-run aggregate supply curve $LRAS$, and short-run aggregate supply curve $SRAS$.
AD, long-run aggregate supply curve LRAS, and short-run aggregate supply curve SRAS at
the natural level of output \(Y_N\) and price level \(P_E\). At point \(E\), the economy is in long-run
equilibrium and, therefore, also in short-run equilibrium. Suppose that now there is an
unexpected rightward shift in the aggregate demand curve from \(AD\) to \(AD'\). This causes
prices to rise, but if firms do not immediately realize that all prices are rising and by mistake
believe that only the price of the products they sell are rising, they will increase output.
This defines the new short-run equilibrium point \(A\) at the intersection of the \(AD'\) and the
\(SRAS\) curves. At point \(A\), the price is \(P_A\) and the level of output of the nation \(Y_A\), which
exceeds the natural level of output of \(Y_N\).

As firms realize that all prices (including their costs of production) have in fact increased,
the \(SRAS\) curve will shift up to \(SRAS'\). The intersection of the \(AD'\) and the \(SRAS'\) curves on
the \(LRAS\) curve defines the new long-run equilibrium point \(C\) at the higher price of
\(P_C\) and natural level of output of \(Y_N\). The price level is now higher but the level of
output has returned to its long-run natural level. The short-run increase in output resulting
from imperfect information or market imperfection is entirely eliminated in the long run as
firms realize that all prices, and hence their costs, have increased proportionately and cut
production back to their long-run natural level. That is, in the long run, as expected prices
rise to match actual prices, the \(SRAS\) curve shifts up by the increase in the price level, and
the nation’s output returns to its lower long-run natural level.

Another way of explaining this is to say that an unexpected increase in aggregate demand
leads to an unexpected increase in prices and a temporary increase in output. As expected
prices increase in the long run to match the increase in actual prices, the short-run aggregate
supply curve shifts up until it crosses the new and higher aggregate demand curve on the
given long-run aggregate supply curve, so that the economy is once again simultaneously
in long-run and short-run equilibrium at its natural level of output. Thus, a particular \(SRAS\)
curve is based on specific expected prices. When expected prices increase in the long run
and match actual prices, the entire \(SRAS\) curve shifts up by the increase in expected prices.
A point to the right of the \(LRAS\) curve means that actual prices exceed expected prices.
Expected prices then increase and this shifts the \(SRAS\) curve upward until expected
prices are equal to actual prices, and the economy returns to its long-run natural level of
output equilibrium. Note that the economy is in short-run equilibrium at the intersection of
any \(AD\) and \(SRAS\) curve. For the economy also to be in long-run equilibrium, the \(AD\) and
\(SRAS\) curves must intersect on the \(LRAS\) curve.

In the absence of imperfect information or market imperfection (i.e., if firms did real-
ize immediately that the increase in aggregate demand increased all prices so that price
expectations always and immediately matched actual prices), then the nation would move
immediately from equilibrium point \(E\) to equilibrium point \(C\), without the intermediate
movement to equilibrium point \(A\) in the short run. In that case, the nation’s output would
never deviate from its long-run natural level, and the nation’s short-run aggregate supply
curve would be vertical and coincide with the long-run aggregate supply curve. It is only
because of imperfect information and market imperfections that short-run deviations in output
from the long-run natural level occur in the real world (see Case Study 19-1). Of course,
a downward shift in the aggregate demand curve would result in a temporary reduction in
output and a permanent reduction in price (see Problem 6, with answer at the end of the book).
19.3 Aggregate Demand in an Open Economy under Fixed and Flexible Exchange Rates

■ CASE STUDY 19-1 Deviations of Short-Run Outputs from the Natural Level in the United States

Figure 19.4 plots the gross domestic product (GDP) deflator on the horizontal axis (with 1971 = 100) as a measure of price increases and the adjusted growth of real GDP (with 1971 = 100) on the vertical axis for the United States from 1971 to 2011. The adjusted growth of real GDP was obtained by subtracting from the growth of real GDP in the United States in each year the average U.S. long-term real growth of 2.8 percent per year. Thus, the adjusted growth of real GDP provides an estimate of the short-run deviations of growth in real GDP from its long-run natural level (the horizontal line at the level of 100, after removing the 2.8 percent long-term growth trend) in the United States in each year. From the figure, we see that the adjusted or short-run growth in the United States temporarily deviated above and below its long-run natural rate, as predicted by theory, despite increases in the price level (GDP deflator) and other short-run disturbances. Note that Figure 19.4 is similar to Figures 19.2 and 19.3 except that the GDP deflator is plotted along the horizontal axis and the adjusted growth of real GDP is plotted along the vertical axis, rather than vice versa.

Figure 19.4. Short-Run Output Deviations from the Natural Level in the United States. The adjusted or short-run growth of real GDP in the United States (with 1971 = 100) deviated above and below its natural or long-run level (the horizontal line at the level of 100 after removing the 3 percent long-term growth trend), but only temporarily, as predicted by theory, despite increases in prices (GDP deflator) and other short-run disturbances. 19.3 Aggregate Demand in an Open Economy under Fixed and Flexible Exchange Rates

Although important long-run supply effects can result, opening the economy affects primarily aggregate demand in the short and medium runs (the time frame for most economic policies). In this section, we examine the aggregate demand effects of opening up the
economy, first in the case of fixed exchange rates and then under flexible exchange rates. To reflect the high (though not perfect) international capital mobility among industrial countries today, we will draw the $\text{BP}$ curve (which refers to the balance of payments) as positively sloped but flatter than the $\text{LM}$ curve.

### 19.3A Aggregate Demand in an Open Economy under Fixed Exchange Rates

Figure 19.5 shows the derivation of an open economy’s aggregate demand curve under fixed exchange rates and compares it to the aggregate demand curve derived in Figure 19.1 for the closed economy. The left panel of Figure 19.5 shows original equilibrium point $E$ in the goods and money markets and in the balance of payments at $i_E$ and $Y_E$, as in Figure 18.2 (except that now the $\text{BP}$ curve is flatter than the $\text{LM}$ curve). This gives point $E$ in the right panel of Figure 19.5.

Suppose now that prices in the nation rise from $P_E$ to $P'$. This reduces the real value of the nation’s given money supply and causes the $\text{LM}$ curve to shift to the left to $LM'$, exactly as in the closed-economy case. With the economy now open, however, there is an additional international effect that must be considered in deriving the nation’s aggregate demand curve. That is, the increase in domestic prices from $P_E$ to $P'$ also reduces the nation’s exports and increases the nation’s imports and causes the $\text{IS}$ and the $\text{BP}$ curves also to shift to the left to, say, $\text{IS}'$ and $\text{BP}'$. The $\text{IS}$ curve shifts to the left because of the worsened trade balance. The $\text{BP}$ curve shifts to the left because higher interest rates are now required at each level of income to attract sufficient additional capital from abroad to compensate for the worsened trade balance that results from the increase in domestic prices.

The intersection of the $\text{LM}'$, $\text{BP}'$, and $\text{IS}'$ curves in the left panel of Figure 19.5 determines new equilibrium point $E''$. At point $E''$, the interest rate ($i_E$) happens to be the same.

---

**FIGURE 19.5.** Derivation of a Nation’s Aggregate Demand Curve under Fixed Exchange Rates.

From equilibrium point $E$ at the intersection of the $\text{LM}$, $\text{IS}$, and $\text{BP}$ curves at price level $P_E$ and income $Y_E$ in the left panel, we get point $E$ in the right panel. An increase in the price level to $P'$ causes the $\text{LM}$, $\text{BP}$, and $\text{IS}$ curves to shift to the left to $LM'$, $BP'$ and $IS'$, thus defining new equilibrium point $E'$, where these curves intersect. By joining points $E$ and $E'$ in the right panel, we derive open-economy aggregate demand curve $AD'$, which is flatter or more elastic than closed-economy aggregate demand curve $AD$. 
19.3 Aggregate Demand in an Open Economy under Fixed and Flexible Exchange Rates

as at the original equilibrium point \( E \) before the increase in prices in the nation, but prices are higher (\( P' \) instead of \( P_E \)), and the level of national income is lower (\( Y'' \) instead of \( Y_E \)). This gives point \( E'' \) in the right panel of Figure 19.5. Joining points \( E \) and \( E'' \) in the right panel gives demand curve \( AD' \) for this open economy. Note that \( AD' \) is flatter or more elastic than closed-economy aggregate demand curve \( AD \) derived earlier because when the economy is open we have the additional effect resulting from international trade and international capital flows that was not present when the economy was closed. Furthermore, the more responsive exports and imports are to the change in domestic prices, the more elastic the \( AD' \) curve is in relation to the \( AD \) curve (assuming, of course, that the Marshall–Lerner condition is satisfied—see Section 16.4b).

How do we know that the \( LM' \) and \( IS' \) curves intersect exactly on the \( BP' \) curve (as at point \( E'' \) in the left panel of Figure 19.5) so that the nation would be once again simultaneously in equilibrium in all three markets? The answer is that if the \( LM' \) curve intersected the \( IS' \) curve at a point above the \( BP' \) curve, the interest rate in the nation would be higher than required for balance-of-payments equilibrium. The nation would then have a surplus in the balance of payments. Under a fixed exchange rate system, the surplus in the nation’s balance of payments would result in an inflow of international reserves and thus an increase in the nation’s money supply, which would shift the \( LM' \) down sufficiently to intersect the \( IS' \) curve on the \( BP' \) curve, so that the nation would be simultaneously in equilibrium in the goods and money markets and in the balance of payments, as at point \( E'' \). The opposite would occur if the \( LM' \) and \( IS' \) curves crossed below the \( BP' \) curve.

19.3B Aggregate Demand in an Open Economy under Flexible Exchange Rates

Figure 19.6 shows the derivation of an open economy’s aggregate demand curve under flexible exchange rates and compares it to the aggregate demand curve that we derived in Figure 19.1 for the closed economy and in Figure 19.5 for an open economy under fixed exchange rates. The left panel of Figure 19.6 shows original equilibrium point \( E \) in the goods and money markets and in the balance of payments at \( i_E \) and \( Y_E \), as in Figure 19.5. This gives point \( E \) in the right panel of Figure 19.6.

Now suppose that prices in the nation rise from \( P_E \) to \( P' \). This reduces the real value of the nation’s given money supply and causes the \( LM \) curve to shift to the left to \( LM' \). The increase in domestic prices also reduces the nation’s exports and increases the nation’s imports and causes the \( IS \) and the \( BP \) curves to also shift to the left to, say, \( IS' \) and \( BP' \) exactly as in Figure 19.5. Now, however, the \( LM' \) and \( IS' \) curves cross at point \( E'' \), which is above the \( BP' \) curve (point \( H \)). This means that the nation has a surplus in its balance of payments. With flexible exchange rates, this means that the nation’s money supply increasing and shifting the \( LM \) curve to the right (as in the case of fixed exchange rates), the nation’s currency appreciates so that the \( BP' \) curve shifts to the left again to \( BP'' \). This causes a further deterioration in the nation’s trade balance and a further shift of the nation’s \( IS' \) curve to \( IS'' \) until the \( LM' \) and \( IS'' \) curves intersect on the \( BP'' \) curve at point \( E^* \), and the nation is once again simultaneously in equilibrium in the goods and services and money markets and in the balance of payments. This gives point \( E^* \) in the right panel. Joining points \( E \) and \( E^* \) in the right panel gives aggregate demand curve \( AD^* \), which is flatter or more elastic than either \( AD \) or \( AD' \).
Prices and Output in an Open Economy: Aggregate Demand and Aggregate Supply

![Diagram of IS-LM-BP curves]

FIGURE 19.6. Derivation of the Nation’s Aggregate Demand Curve under Flexible Exchange Rates. Starting from equilibrium point $E$ in the left and right panels, an increase in the price level to $P'$ causes the $LM$, $BP$, and $IS$ curves to shift to the left to $LM'$, $BP'$, and $IS'$. Since the $LM'$ and $IS'$ curves intersect above the $BP'$ curve (i.e., point $E'$ is above point $H$), the nation has a surplus in its balance of payments. The nation’s currency then appreciates (i.e., the $BP'$ curve shifts to the left to $BP''$). This causes the $IS'$ curve to shift further to the left to $IS''$ until the $LM'$ and the $IS''$ curves intersect on the $BP''$ curve at point $E''$. This gives point $E''$ in the right panel. Joining points $E$ and $E''$ in the right panel gives aggregate demand curve $AD''$, which is more elastic than $AD$ and $AD'$.

Note that in the left panel of Figure 19.6, the interest rate at equilibrium point $E^*$ is equal to $i_E$ (the interest rate at the original equilibrium level), but this is only by coincidence. That is, $i''$ can also be higher or lower than $i_E$, depending on where the $LM'$, $BP''$, and $IS''$ curves intersect. Note that if the $LM'$ and $IS'$ curves intersected below the $BP'$ curve rather than above it as in the left panel of Figure 19.6 (i.e., if point $E^*$ had been below rather than above point $H$), then the nation would have a deficit in its balance of payments. In that case, the nation’s currency would depreciate (i.e., the $BP'$ curve would shift to the right and so would the $IS'$ curve) until the $LM'$ and $IS'$ curves intersected on the $BP''$ curve and the nation was in equilibrium in all three markets. If the $LM'$ and $IS'$ curves intersected on the $BP'$ curve, there would be no change in the nation’s exchange rate and no further shift in the $BP'$ and $IS'$ curves, so that the result would be the same as under fixed exchange rates.

19.4 Effect of Economic Shocks and Macroeconomic Policies on Aggregate Demand in Open Economies with Flexible Prices

In the real world, any change that affects the $IS$, $LM$, or $BP$ curves can affect the nation’s aggregate demand curve, depending on whether the nation operates under fixed or flexible exchange rates. In this section, we examine the effect of real and monetary shocks as well as fiscal and monetary policies on aggregate demand in open economies with flexible prices under fixed and flexible exchange rates.
19.4 Effect of Economic Shocks and Macroeconomic Policies on Aggregate Demand

19.4A Real-Sector Shocks and Aggregate Demand

Starting from equilibrium point $E$ in both panels of Figure 19.7, suppose that the nation’s exports increase or the nation’s imports decrease because of an increase in foreign prices or a change in tastes at home or abroad. The increase in the nation’s exports or reduction in the nation’s imports in the face of constant domestic prices leads to an improvement in the nation’s trade balance and causes the nation’s $IS$ and $BP$ curves to shift to the right to $IS'$ and $BP'$. Since the intersection of the $IS'$ and $LM$ curves at point $E'$ is above the $BP'$ curve, the nation would have a surplus in its balance of payments. Under fixed exchange rates, this leads to an inflow of international reserves and an increase in the nation’s money supply, which causes a rightward shift in the $LM$ curve to $LM'$, thus defining new equilibrium point $E''$. The movement from point $E$ to point $E''$ in the left panel of Figure 19.7 is shown by the shift in the nation’s aggregate demand curve from $AD$ to $AD''$ in the right panel. That is, at the given domestic price of $P_E$, the nation’s output is now $Y''$ instead of $Y$ because of the autonomous increase in the nation’s exports or reduction in the nation’s imports.

The result is different if the nation had flexible exchange rates, but we can still utilize Figure 19.7 to analyze this case. With flexible exchange rates, the potential surplus in the nation’s balance of payments resulting at point $E'$ in the left panel of Figure 19.7 leads to an appreciation of the nation’s currency and a leftward shift of the $BP'$ curve back to its original position of $BP$ (instead of the nation’s money supply increasing and causing the $LM$ curve to shift to the right to $LM'$, as in the fixed exchange rate case). The appreciation of the nation’s currency (and leftward shift of the $BP'$ curve back to $BP$) is accompanied by a leftward shift in the $IS'$ curve back to its original $IS$ position (as the trade balance returns to its original level as a result of the appreciation of the nation’s currency). Thus, an autonomous improvement in the nation’s trade balance has no lasting effect on the nation’s

---

**FIGURE 19.7.** Changes in the Nation’s Trade Balance and Aggregate Demand. Starting from point $E$ in both panels, an increase in the nation’s exports and/or reduction in the nation’s imports with unchanged domestic prices causes the $IS$ and $BP$ curves to shift rightward to $IS'$ and $BP'$. Under fixed exchange rates, this leads to a surplus in the nation’s balance of payments and a rightward shift of the $LM$ curve to $LM'$, which defines new equilibrium point $E'$. Thus, the $AD$ curve shifts rightward to $AD''$. With flexible exchange rates, the nation’s currency appreciates so that the $BP'$ and $IS'$ curves shift back to $BP$ and $IS$ at original equilibrium point $E$ in both panels.
level of output and aggregate demand (i.e., the nation returns to equilibrium point \( E \) in the left panel and point \( E \) on aggregate demand curve \( AD \) in the right panel) under flexible exchange rates. An autonomous worsening of the nation’s trade balance would have the opposite effect.

### 19.4B Monetary Shocks and Aggregate Demand

Starting from equilibrium point \( E \) in both panels of Figure 19.8, suppose that there is a short-term capital inflow to or reduced capital outflow from the nation as a result of a reduction in interest rates abroad or a change in tastes at home or abroad. This leads to a rightward shift of the \( BP \) curve to \( BP' \) in both panels. With fixed exchange rates, the fact that point \( E \) is above the \( BP' \) curve means that the nation has a surplus in its balance of payments (see the left panel of Figure 19.8). This leads to an inflow of international reserves and an increase in the nation’s money supply, which cause the nation’s \( LM \) curve to shift to the right to \( LM' \), thus defining new equilibrium point \( E'' \) at higher income \( Y'' \). Since domestic prices are unchanged at the higher level of national income, this means that the nation’s aggregate demand curve (not shown in the figure) shifts to the right.

If, on the other hand, the nation operated under flexible exchange rates, the rightward shift in the \( BP \) curve to \( BP' \) leads to a potential surplus in the nation’s balance of payments (see the right panel of Figure 19.8). This causes the nation’s currency to appreciate so that the nation’s trade balance worsens. These changes are shown by a leftward shift of the \( BP' \) and \( IS \) curves to \( BP'' \) and \( IS' \) until new equilibrium point \( E'' \) is reached, at which the \( LM \), \( BP'' \), and \( IS' \) curves intersect at the given price level and lower national income of \( Y'' \).

---

**FIGURE 19.8. Short-Term Capital Flows and Aggregate Demand.**

Starting from equilibrium point \( E \) in both panels, an autonomous short-term capital inflow with unchanged domestic prices and fixed exchange rates causes the nation’s \( BP \) and \( LM \) curves to shift rightward to \( BP' \) and \( LM' \), thus defining new equilibrium point \( E'' \) with higher national income \( Y'' \) in the left panel. Thus, the nation’s aggregate demand curve (not shown in the figure) shifts to the right. With flexible exchange rates (the right panel), the nation’s currency appreciates, so that the \( BP' \) and \( IS \) curves shift to the left to \( BP'' \) and \( IS' \), and they define new equilibrium point \( E'' \) along the original \( LM \) curve, so that the nation’s aggregate demand curve shifts to the left.
19.4 Effect of Economic Shocks and Macroeconomic Policies on Aggregate Demand

As a result, the nation’s aggregate demand curve (not shown in the figure) shifts to the left. Thus, a short-term capital inflow leads to a rightward shift of the nation’s aggregate demand curve under fixed exchange rates but a leftward shift under flexible rates. The exact opposite occurs with an autonomous short-term capital outflow from the nation.

19.4c Fiscal and Monetary Policies and Aggregate Demand in Open Economies

We have seen in Section 18.4c that under highly elastic short-term international capital flows (i.e., with the $BP$ curve flatter than the $LM$ curve) fiscal policy is effective while monetary policy is not, whereas the opposite is the case under flexible rates.

Specifically, under fixed exchange rates and highly elastic short-term international capital flows, expansionary fiscal policy will lead to capital inflows and is very effective in shifting the nation’s aggregate demand curve to the right. Similarly, contractionary fiscal policy will lead to capital outflows and is very effective in shifting the nation’s aggregate demand curve to the left. On the other hand, under fixed exchange rates and high international capital flows, monetary policy is not effective because any attempt by the nation to lower interest rates by increasing the nation’s money supply (easy monetary policy) will simply lead to a capital outflow with little if any effect on the nation’s aggregate demand.

Under flexible exchange rates and high international short-term capital flows, the opposite is the case. That is, easy monetary policy will be very effective in shifting the nation’s aggregate demand curve to the right, and tight monetary policy will be effective in shifting the nation’s demand curve to the left. On the other hand, fiscal policy will be ineffective since short-term international capital flows will offset much of the effect of any fiscal policy. Thus, in examining the effect of macroeconomic policies in open economies with flexible prices and highly elastic short-term international capital flows, we will concentrate on fiscal policy under fixed exchange rates and on monetary policy under flexible exchange rates.

We can summarize the effect of economic shocks and macroeconomic policies on aggregate demand under the present conditions of highly elastic short-term international capital flows and flexible prices as follows:

1. Any shock that affects the real sector of the economy affects the nation’s aggregate demand ($AD$) curve under fixed exchange rates but not under flexible exchange rates. For example, an autonomous improvement in the nation’s trade balance shifts the $AD$ curve to the right under fixed exchange rates but not under flexible exchange rates. The reverse is also true.

2. Any monetary shock affects the nation’s aggregate demand curve under both fixed and flexible exchange rates—but in opposite directions. For example, an autonomous increase in short-term capital inflows to the nation causes the nation’s $AD$ curve to shift to the right under fixed exchange rates and to the left under flexible exchange rates. The reverse is also true.

3. Fiscal policy is effective under fixed exchange rates but not under flexible exchange rates. The opposite is true for monetary policy. For example, expansionary fiscal policy—but not monetary policy—can be used to shift the $AD$ curve to the right under fixed exchange rates, but monetary policy—not fiscal policy—can be used to shift the nation’s $AD$ curve to the right under flexible exchange rates.
19.5 Effect of Fiscal and Monetary Policies in Open Economies with Flexible Prices

We have seen in the previous section that under fixed exchange rates and highly elastic short-term international capital flows, fiscal policy is effective whereas monetary policy is ineffective. On the other hand, with flexible exchange rates, monetary policy is effective and fiscal policy is not. Thus, we examine here fiscal policy under fixed exchange rates and monetary policy under flexible rates.

Let us begin by examining the effect of expansionary fiscal policy under fixed exchange rates from initial equilibrium point \( E \), where the \( AD \) and \( SRAS \) curves cross on the \( LRAS \) curve at the nation’s natural level of output of \( Y_N \) and price level of \( P_E \) in the left panel of Figure 19.9 (as in Figure 19.3). An expansionary fiscal policy that shifts the \( AD \) curve up to \( AD' \) defines new short-run equilibrium point \( A \) at the intersection of the \( AD' \) and \( SRAS \) curves at \( P_A \) and \( Y_A \), with \( Y_A > Y_N \). The temporary expansion of output to \( Y_A \) occurs because of market imperfections or imperfect information as described in Section 19.3 for a closed economy. That occurs because firms originally believe that only the price of the products they sell has increased and actual prices temporarily exceed expected prices.

Over time, however, as firms realize that all prices (including their costs of production) have increased, the \( SRAS \) curve will shift up to \( SRAS' \). The intersection of the \( AD' \) and the \( SRAS' \) curves on the \( LRAS \) curve defines new long-run equilibrium point \( C \) at the higher price of \( P_C \) and natural level of output of \( Y_N \). The price level is now higher, but the level

![Figure 19.9](image-url)

**Figure 19.9.** Expansionary Fiscal Policy from the Natural Level of Output and Recession under Fixed Exchange Rates.

Starting from long-run equilibrium point \( E \) in the left panel, expansionary fiscal policy shifts the \( AD \) curve up to \( AD' \) and defines short-run equilibrium point \( A \) at \( P_A \) and \( Y_A > Y_N \). In the long run, the \( SRAS \) curve shifts up to \( SRAS' \) defining equilibrium point \( C \) at \( P_C \) and \( Y_N \). Starting from recession point \( R \) in the right panel with \( P_R \) and \( Y_R < Y_N \), the nation could use expansionary fiscal policy to shift the \( AD \) curve up to \( AD' \) so as to reach equilibrium point \( C \) at \( P_C \) and \( Y_N \) at the intersection of the \( AD' \), \( SRAS \), and \( LRAS \) curves. The nation, however, could in time have reached equilibrium point \( E \) at \( P_E \) and \( Y_N \) automatically as a result of falling domestic prices because of recession and the \( SRAS \) curve shifting down to \( SRAS' \).
of output has returned to its lower long-run natural level. The short-run increase in output is entirely eliminated in the long run as expected prices rise to match the increase in actual prices. Note that this is exactly the same as in the closed-economy case. The only difference is that now we are dealing with an open economy. But if we assume, as we do, that the effect of openness in the economy has already been incorporated into the $AD$ and $AD'$ curves, the process by which the nation’s output temporarily exceeds but then returns to its long-term natural level at higher prices is exactly the same. More interesting and realistic is the case where the nation uses expansionary fiscal policy from a condition of recession, such as point $R$ at $P_R$ and $Y_R < Y_N$ in the right panel of Figure 19.9. Starting from point $R$ in the right panel, the expansionary fiscal policy that shifts the $AD$ curve to the right at $AD'$ results in new long-run equilibrium point $C$, where the $AD'$ and $SRAS$ curves intersect on the $LRAS$ curve at higher price level $P_C$ and natural level of output $Y_N$. Note that the movement for short-run equilibrium point $R$ to long-run equilibrium point $C$ now involves a movement along the $SRAS$ curve.

The nation, however, could have reached equilibrium point $E$ in the long run at the intersection of the $AD$ and $SRAS'$ curves on the $LRAS$ curve without any expansionary fiscal policy by simply allowing market forces to work themselves out. That is, because at point $R$ output level $Y_R$ is below the natural output level of $Y_N$, all prices, including firms’ costs, are expected to fall, and as prices actually fall, the $SRAS$ curve shifts down to $SRAS'$, so as to intersect the unchanged $AD$ curve at point $E$ on the $LRAS$ curve. The nation is now at long-run and short-run equilibrium at the natural level of output of $Y_N$ and lower price level $P_E$. Note that the movement down the given $AD$ curve from point $R$ to point $E$ reflects not only the closed-economy increase in the aggregate quantity of goods and services demanded as a result of lower domestic prices (as described in Section 19.2a) but also the improvement in the nation’s trade balance as a result of lower domestic prices (as described in Section 19.3).

But why then should the nation adopt an expansionary fiscal policy to overcome the recession at point $R$ if this causes inflation, if the recession would be automatically eliminated anyway by lower prices? The reason is that waiting for market forces to overcome the recession might take too long. This is especially likely to be the case if prices are not very flexible downward. Economists who believe that prices are sticky and not very flexible downward favor the use of expansionary fiscal policy. Those who believe that expansionary fiscal policy leads to the expectation of further price increases and inflation prefer that a recession be corrected automatically by market forces without any expansionary fiscal policy.

The effect of monetary policy under flexible exchange rates is qualitatively the same as the effect of fiscal policy under fixed exchange rates (and so we can continue to use Figure 19.9) once we have incorporated into the nation’s aggregate demand curve the different adjustment taking place under flexible exchange rates rather than under fixed exchange rates. That is, starting from a position of long-run equilibrium, an easy monetary policy shifts the $AD$ curve to the right, and this leads to a temporary expansion of the nation’s output. In the long run, however, as expected prices rise to match the increase in actual prices, the $SRAS$ curve shifts up and defines a new equilibrium point at the natural level of output but higher prices.

With flexible exchange rates, the nation’s currency will also have depreciated. Similarly, starting from a position of recession, monetary policy can speed the movement to the higher natural level of output but only at the expense of higher prices. The alternative is for the economy to allow the recession to be corrected automatically by market forces. In that case, the nation would end up with lower prices and an appreciated currency. The problem,
Figure 19.10 shows the relationship between central bank independence and average inflation in industrial countries from 1955 to 1988. The figure shows that nations with more independent central banks (Germany, Switzerland, and the United States) have had less inflation than nations with less independent central banks (New Zealand, Spain, Italy, the United Kingdom, and France). Specifically, when excessively expansionary fiscal policies push up interest rates and cause an appreciation in the nation’s currency, monetary authorities come under increasing pressure from the electorate and fiscal policymakers to counter such effects by expanding the money supply to “accommodate” the increased money demand. If monetary authorities do not resist such pressures (i.e., if the central bank is not sufficiently independent) and comply, the outcome will be inflation. In the United States, the Fed (which operates as the U.S. central bank) is semiautonomous and to a large extent independent of the executive branch, which is in charge of expenditures and taxation (fiscal policy). Thus, the United States has had a better inflation performance than the United Kingdom or France with less independent central banks. In recessionary periods, elected officials and the electorate generally demand easier or more expansionary monetary policy under the threat of reduced central bank independence. A case in point was the 1991–1992 recession in the United States, when the Fed came under strong pressure to ease monetary policy. The Fed needed no prodding and slashed interest rates six times—from 6.5 percent to 1.0 percent—during the 2001 recession.

**FIGURE 19.10.** Index of Central Bank Independence and Average Inflation.
Nations such as Germany, Switzerland, and the United States with more independent central banks have had less inflation than nations such as New Zealand, Spain, Italy, the United Kingdom, and France with less independent central banks.
Starting in 1990, some nations adopted inflation targeting as a new approach to monetary policy based on achieving a specific target for inflation. What makes this approach new and different is the explicit public commitment to control inflation with transparency and accountability. By 2012, 26 countries (about half developed and half developing) had adopted the policy (see Table 19.1). Furthermore, the U.S. Federal Reserve, the European Central Bank, the Bank of Japan, and the Swiss National Bank have also adopted many of the main elements of inflation targeting, and others are moving in that direction. In general, inflation-targeting nations seek to achieve the inflation target over the medium term (usually over a two- to three-year horizon) rather than at all times.

Table 19.1 indicates the nations that adopted inflation targeting, the date that they adopted it, the inflation rate at the adoption date, the average inflation rate in 2009, and the target inflation rate (given either as a range or as a rate, plus or minus a specified percentage, usually 1 percent). Although inflation and growth rates improved in most countries over the 1991–2009 period, inflation targeters improved more, experienced less volatility in inflation and growth, and were less adversely affected by global economic crises than other countries.

</table>

However, is that if prices are sticky and not too flexible downward, then the process may take too long. In that case, the cost of inflation from easy monetary policy may be lower than the large opportunity cost of lost output and employment from a protracted recession. There is some evidence that nations with more independent central banks suffer less inflation than nations with central banks that are less independent and more responsive to political pressures (see Case Study 19-2) and so do nations that adopt inflation targeting (see Case Study 19-3).

19.6 Macroeconomic Policies to Stimulate Growth and Adjust to Supply Shocks

In this section, we examine fiscal and monetary policies to stimulate long-run growth and adjust to supply shocks in open economies with flexible prices.

19.6A Macroeconomic Policies for Growth

Although fiscal and monetary policies are used primarily to affect aggregate demand in the short and medium runs, they can also be used to stimulate long-run growth in the economy (i.e., to shift the LRAS curve to the right). Governments can stimulate long-run growth by increasing expenditures on education, infrastructures, basic research, and to improve the functioning of markets. Governments can also stimulate long-run growth by tax incentives and low long-term interest rates to encourage private investment. It must be pointed out, however, that the process of long-run growth is not yet entirely understood. To the extent that efforts to stimulate long-run growth in the economy are successful, however, they will shift the nation’s LRAS curve to the right, leading to more employment, higher incomes, lower prices, and possibly an appreciated currency in the long run.

The use of expansionary macroeconomic (i.e., fiscal and monetary) policies to stimulate growth can be examined with Figure 19.11. We begin at long-run equilibrium point $E$ where the nation’s $AD$ and $SRAS$ curves intersect on the LRAS curve at $P_E$ and $Y_N$. Suppose that now the nation uses expansionary fiscal and/or monetary policies to stimulate long-run growth. The $AD$ curve then shifts to the right to, say, $AD'$, so that the nation reaches new short-run equilibrium point $A$ at $P_A$ and $Y_A > Y_N$. (So far, this is the same as in the left panel of Figure 19.9.) To the extent that the expansionary macroeconomic policies do in fact stimulate long-run growth, however, the $LRAS$ and $SRAS$ curves shift to the right to LRAS' and SRAS'' and define new long-run equilibrium point $G$ at $P_G$ (= $P_E$) and $Y'_N > Y_N$ at the intersection of the LRAS’, SRAS”', and AD’ curves (see Figure 19.11).

Growth has led to a higher level of natural output and no increase in prices in relation to original equilibrium point $E$. Thus, instead of expansionary macroeconomic policy leading to an upward shift in the SRAS curve and the same original level of natural output and much higher prices in the long run in the absence of growth (point $C$, as in the left panel of Figure 19.9), with growth, the nation reaches a higher level of natural output and no long-run increase in prices. With growth, however, prices could be higher or lower as compared with the original long-run equilibrium level. It all depends on how far to the right the LRAS and SRAS curves shift in relation to the AD curve as a result of expansionary macroeconomic policies aimed at growth. The greater is the rightward shift in the LRAS and SRAS curves
19.6 Macroeconomic Policies to Stimulate Growth and Adjust to Supply Shocks

Starting at original long-run equilibrium point $E$, expansionary macroeconomic policies for growth shift the $AD$ curve to the right to $AD'$ and define new short-run equilibrium point $A$ at $P_A > P_E$ and $Y_A > Y_N$. With long-run growth, the LRAS and SRAS curves shift to the right to LRAS' and SRAS'' and define equilibrium point $G$ at $P_G = P_E$ and $Y_N' > Y_N$.

In relation to the $AD$ curve, the greater is the increase in the natural level of output in the nation and the more likely it is that prices will be lower in the long run.

19.6b Macroeconomic Policies to Adjust to Supply Shocks

Macroeconomic policies can also be used to adjust to supply shocks. The most notorious of the postwar supply shocks was the sharp increase in petroleum prices engineered by OPEC (Organization of Petroleum Exporting Countries) between the autumn of 1973 and the end of 1974, and again from 1979 to 1981. The increase in petroleum prices increased production costs in all petroleum-importing countries and caused a leftward shift in their short-run and long-run supply curves. The effect on aggregate demand was less clear. At first sight, it might seem that petroleum-importing nations would suffer a deterioration of their balance of payments, a depreciation of their currencies, and thus a shift to the right in their aggregate demand curves. On closer reflection, however, we find that this need not be the case. The reason follows.

It is true that, because the demand for petroleum is inelastic, an increase in price led to higher total expenditures in all nonpetroleum-producing countries to purchase this crucial input. But the reduction in the natural level of output that accompanied the petroleum shock also induced a reduction in all other imports. Thus, the trade balance of petroleum-importing nations could worsen or improve, depending on which of these two opposing forces was stronger. But there is more. The $BP$ curve refers to the balance of payments as a whole,
which includes both the trade balance and the balance on capital account. Thus, even if importing nations’ trade balances deteriorated as the direct result of the increase in petroleum prices, their capital account could also improve if OPEC nations invested their higher petroleum earnings in industrial nations. This is in fact exactly what happened with the United States. Thus, it is impossible to determine a priori the net effect on importing nations’ balance of payments resulting from the increases in petroleum prices. And if we look at the data, we find that the balance of payments improved in some nations and in some years and worsened in others after the two oil shocks; therefore, no general conclusion can be reached. In what follows, therefore, we assume that the aggregate demand curve of petroleum-importing nations remains unchanged as a result of the increase in petroleum prices. It would be a simple matter, however, to examine the situation where this is not the case, and that is left as an exercise.

With the above in mind, we can proceed to use our aggregate demand and aggregate supply framework to analyze the effect of a petroleum shock on industrial nations and the possible macroeconomic policies required to adjust to these shocks. This is done in Figure 19.12. We start at original long-run equilibrium point $E$ with $P_E$ and $Y_N$ at the intersection of the $LRAS$, $SRAS$, and $AD$ curves. The immediate effect of a large increase
19.6 Macroeconomic Policies to Stimulate Growth and Adjust to Supply Shocks

CASE STUDY 19-4 Petroleum Shocks and Stagflation in the United States

Figure 19.13 shows the inflation rate and the rate of unemployment in the United States from 1970 to 2011. The periods of stagflation (shaded in the figure), from the end of 1973 to the middle of 1975 and from the middle of 1979 to the end of 1982 with high inflation and high unemployment, are clearly associated with the two petroleum shocks. Since 1990, the rate of inflation in the United States has closely mirrored the price of petroleum, falling and rising together, while the rate of unemployment continued to fall from 1992 to 2000. The rate of unemployment then rose from 2000 to 2003, fell from 2003 to 2006, rose from 2007 to 2010 as a result of recession, and remained high in 2011 because of the slow recovery. The rate of unemployment remained relatively low up to 2007 and the rate of inflation until 2011, however, despite high petroleum prices.

in petroleum prices is to shift the nation’s short-run aggregate supply curve from \( SRAS \) to, say, \( SRAS' \), thus defining at the intersection of the \( SRAS' \) and \( AD \) curves the new short-run equilibrium point \( E' \) with \( P' > P_E \) and \( Y'_N < Y_N \). The combination of recession or stagnation and higher prices or inflation at point \( E' \) is referred to as stagflation.

The lower level of natural output and employment at \( Y'_N \), however, causes prices to fall, thus lowering costs and shifting the \( SRAS' \) curve down and to the right, but not all the way back to \( SRAS \). The reason is that long-run production costs have also increased as a result of the increase in petroleum prices, and so the \( LRAS' \) curve has also shifted to the left, say, to \( LRAS' \). Thus, the new long-run equilibrium point \( E'' \) is obtained at the intersection of the \( LRAS', SRAS', \) and \( AD \) curves at \( P'' < P' \) and \( Y''_N > Y'_N \). At point \( E'' \), prices are higher and the natural level of output and employment is lower than at point \( E' \) before the petroleum shock.

If, instead of waiting for prices to fall and eventually reach long-run equilibrium point \( E'' \), the nation used easy or expansionary monetary policy to shift the aggregate demand curve...
from \( AD \) to \( AD' \) in order to speed up recovery from point \( E' \), the nation would move to equilibrium point \( E^* \) at the intersection of the \( LRAS' \), \( SRAS' \), and \( AD' \) curves, and prices would be even higher. Note that in either case the nation would not get back to the natural output level of \( Y_N \) that prevailed before the supply (petroleum) shock. Nations such as Italy and France that tried to use expansionary monetary policies to fight the stagflation that resulted from the petroleum shock of the 1970s ended up with much higher inflation rates than nations such as Germany and Japan that used tight or contractionary monetary policies to fight inflation, even in the face of recession. Case Study 19-4 clearly shows the two periods of stagflation (recession and inflation) in the United States that resulted from the two petroleum shocks. Case Study 19-5 shows the estimated impact of a $15 increase in the price of petroleum on the United States, Japan, the Euro Area, and all OECD countries. Case Study 19-6 extends the analysis to the relationship between the actual and the natural unemployment rates, on the one hand, and the rate of inflation, on the other, in the United States since 1980.

### CASE STUDY 19-5  Impact of an Increase in the Price of Petroleum

Table 19.2 shows the estimated impact of a sustained or permanent $15 increase in the price of petroleum in the United States, the European Union (EMU), Japan, and in the OECD as whole in 2004 and 2005. The effects are measured as deviations from the baseline scenario and assuming constant interest rates. The table shows that a $15 sustained increase in the price of petroleum reduces the level of U.S. GDP by 0.15 percent (about one-seventh of 1 percent) in 2004 and by 0.35 percent in 2005 from what would have been the case without the increase in the price of petroleum. U.S. inflation would be higher by 0.70 percentage points in 2004 and 0.45 percentage points in 2005, while the U.S. current account deficit as a percentage of GDP would worsen by 0.30 percent in 2004 and 0.25 percent in 2005. The table shows that the impact on the EMU, Japan, and OECD is similar. Since the energy crises of the early 1970s and 1980s, industrial nations have become much more energy efficient and now require only half as much energy to produce each dollar of GDP than they did in the 1970s. This, together with the process of rapid globalization that has been taking place during the past three decades, has dampened the inflationary impact of increases in the price of petroleum.

19.6 Macroeconomic Policies to Stimulate Growth and Adjust to Supply Shocks

■ CASE STUDY 19-6  Actual and Natural Unemployment Rates and Inflation in the United States

Table 19.3 gives the actual unemployment rate and the inflation rate in the United States from 1980 to 2011. Until the mid-1990s, the natural unemployment rate was believed to be about 6 percent in the United States. Any rate of unemployment below 6 percent was supposed to trigger higher inflation. From the table we see that a higher unemployment rate was associated with a lower inflation rate in six of the 14 years from 1980 to 1993 (1982, 1987–1989, 1991–1992). From 1995 to 2007, however, the rate of unemployment fell below the natural level in the United States (except in 2003), but inflation remained very low and even declined in 1997–1998, 2001–2002, and 2006–2007. One explanation that has been given for this phenomenon is that because of the rapid globalization of the world economy, firms try to avoid increasing prices for fear of losing markets to foreign competitors, and workers refrain from demanding excessive wage increases for fear of losing their jobs. In other words, there seems to have occurred a structural change in the U.S. labor market that lowered the natural rate of unemployment from 6 percent in the 1980s to around 4 percent afterward.

SUMMARY

1. In our discussion of open-economy macroeconomics, we have generally assumed until now that prices remained constant as the economy expanded and contracted over the business cycle. In this chapter, we relax the assumption of constant prices and examine the short-run and long-run relationship between price and output in an open economy using an aggregate demand and aggregate supply framework that incorporates the effects of international trade and capital flows.

2. The aggregate demand (AD) curve is derived from the IS–LM curves of Chapter 18. The AD curve slopes downward, indicating that larger quantities of goods and services are demanded in the economy at lower prices. The long-run aggregate supply (LRAS) curve is independent of prices and is vertical at the nation’s natural level of output, which depends on the availability of labor, capital, natural resources, and technology in the nation. The nation’s output can temporarily deviate from its natural level (i.e., the nation’s short-run aggregate supply (SRAS) curve is upward sloping) because of imperfect information or market imperfections. An unexpected increase in aggregate demand leads firms to temporarily increase their output. In the long run, however, as expected prices increase to match the increase in actual prices, the short-run aggregate supply curve shifts up by the amount of the price increase and defines a new long-run equilibrium point at the natural level of output but higher price level.

3. An increase of the price level in the nation causes a leftward shift in the LM curve because of the reduction in the real value of the nation’s money supply. The IS curve shifts to the left because of the worsened trade balance, and the BP curve does the same because higher interest rates are now required to attract more international capital to compensate for the worsened trade balance. An increase in domestic prices thus reduces the aggregate quantity of goods and services demanded in the economy by more than if the economy were closed. The open-economy aggregate demand curve is even flatter or more elastic under flexible exchange rates because an increase in prices and worsened trade balance in the nation usually also lead to exchange rate changes and further trade balance effects.

4. Any change that affects the IS, LM, and BP curves can affect the nation’s aggregate demand curve, depending on whether the nation operates under fixed or flexible exchange rates. An improvement in the nation’s trade balance with constant domestic prices leads to a rightward shift in the nation’s aggregate demand curve under fixed exchange rates but only to an appreciation of the nation’s currency under flexible rates. An autonomous short-term capital inflow to or reduced outflow from the nation results in a rightward shift in the nation’s aggregate demand curve under fixed exchange rates but to a leftward shift under flexible rates. Under highly elastic short-term international capital flows, fiscal policy is effective under fixed exchange rates, whereas monetary policy is ineffective. The opposite is true under flexible rates.

5. Expansionary fiscal policy under fixed exchange rates or monetary policy under flexible rates from a position of long-run equilibrium leads to an increase in prices but to only a temporary expansion in output. A nation could correct a recession with expansionary fiscal policy under fixed exchange rates and easy monetary policy under flexible rates but only at the expense of higher prices. In time, the recession would be automatically eliminated by falling prices, but this may take too long if prices are sticky and not too flexible downward. Nations with more independent central banks have had a better inflation performance than nations with less independent central banks.

6. Macroeconomic policies can also be used to achieve long-run growth. The LRAS and SRAS curves then shift to the right, reaching a larger level of natural output and employment and lower prices than with expansionary macroeconomic policies and no growth. The large supply shocks due to the sharp increases in petroleum prices during the 1970s caused the SRAS and LRAS curves of petroleum-importing countries to shift to the left because of increased production costs. It is less clear what happened to aggregate demand. The leftward shift in SRAS and LRAS curves led to recession and inflation (stagflation) in petroleum-importing countries. Nations that used expansionary monetary policies to fight stagflation generally faced even more inflation than nations that did not.
A LOOK AHEAD

The next chapter examines and compares the advantages and disadvantages of flexible versus fixed exchange rate systems with the objective of determining which type of system is “better.” The evaluation will be conducted in terms of the degree of uncertainty arising under each system, the type of speculation that each system is likely to give rise to, the likely effect of each system on the rate of inflation, and the policy implications of each system. The conclusion will be reached that each system has some advantages and disadvantages and each may be more appropriate under different sets of circumstances. Chapter 20 also examines the European Monetary System (EMS) and macroeconomic policy coordination. Chapter 21 then deals with the operation of the entire international monetary system.

QUESTIONS FOR REVIEW

1. Why is it important to examine the relationship between prices and output in our analysis of open-economy macroeconomics? How are prices incorporated into the analysis of open-economy macroeconomics?
2. What does the aggregate demand curve in a closed economy show? How is it derived? Why is it downward sloping?
3. Why is a reduction in the general price level for a given money supply shown as a movement down a given aggregate demand curve, while an increase in the money supply for a given price level is shown as a shift in the aggregate demand curve?
4. How does an increase in government expenditures affect the AD curve? Why? To what kind of fiscal policy does this refer?
5. What does the aggregate supply curve show? How does the long-run aggregate supply curve differ from the short-run aggregate supply curve?
6. What is the natural level of output?
7. How can a nation’s output temporarily deviate from its natural level? Why and how does a nation’s output return to its long-run natural level?
8. Using an aggregate demand and an aggregate supply framework, explain why a nation must necessarily be in short-run equilibrium if it is in long-run equilibrium. How can the nation be in short-run equilibrium without being in long-run equilibrium?
9. How is an open economy’s aggregate demand curve derived under fixed exchange rates? Why is this more elastic than if the nation were a closed economy?
10. Why must the Marshall–Lerner condition be satisfied for an open economy’s aggregate demand curve to be more elastic than if the economy were closed?
11. How is an open economy’s aggregate demand curve derived under flexible exchange rates? Why is this more elastic than if the nation were a closed economy or for an open economy with fixed exchange rates?
12. How does the effect of a real-sector shock on the nation’s aggregate demand differ under fixed and flexible exchange rates?
13. How does the effect of a monetary shock on the nation’s aggregate demand differ under fixed and flexible exchange rates from the case of a real-sector shock?
14. Why is fiscal policy effective but monetary policy ineffective under fixed exchange rates? Why is the opposite true under flexible rates?
**PROBLEMS**

1. Using an IS–LM diagram, show graphically how a reduction in the general price level in a nation results in a movement down the aggregate demand curve.

2. Using an IS–LM diagram, show graphically that for a given LM curve, the flatter is the IS curve, the flatter or more elastic is the aggregate demand curve.

3. Using an IS–LM diagram, show the effect of an easy monetary policy on the aggregate demand curve.

4. Using an IS–LM diagram, show the effect of an expansionary fiscal policy on the aggregate demand curve.

5. Explain why an unexpected increase in prices in the face of sticky wages (i.e., wages that do not immediately increase in the same proportion as prices) can explain an upward sloping short-run aggregate supply curve.

6. Suppose that the original long-run and short-run equilibrium in the economy of Figure 19.3 were at point C where the AD′ curve crosses the LRAS and SRAS′ curves. Explain why a downward shift in the aggregate demand curve from AD′ to AD would result in a temporary reduction in output and a permanent reduction in price.

7. Explain in terms of labor market imperfections how a downward shift in the aggregate demand curve would result in a temporary reduction in output and a permanent reduction in price.

8. Explain how equilibrium in the goods and money markets and in the balance of payments would be reached if the LM′ curve in the left panel of Figure 19.5 intersected the IS′ curve below the BP′ curve for an economy operating under fixed exchange rates.

9. Draw a figure similar to the left panel of Figure 19.6 showing how equilibrium in the goods and money markets and in the balance of payments would be reached if the LM′ curve intersected the IS′ curve below the BP′ curve for an economy operating under flexible exchange rates.

10. Examine the effect on the nation’s aggregate demand curve of an autonomous worsening of a nation’s trade balance under fixed exchange rates.

11. Do the same as for Problem 10 for flexible exchange rates.

12. Explain why the usefulness of expansionary fiscal policy or easy monetary policy to correct a recession depends on how flexible domestic prices are downward.

13. With reference to Figure 19.12, determine what would happen if the monetary policy that shifts the nation’s aggregate demand curve to the right to AD′ in order to adjust to stagflation also leads to growth that keeps the nation’s long-run aggregate supply curve at LRAS in the long run.

14. Is the concept of the natural rate of unemployment useful in view of the data presented in Case Study 19-5?
